"This research project is supported, in whole or in part, by U.S. Department of Energy grant number DE-FG02-91CE23810: Materials Compatibilities and Lubricants Research (MCLR) on CFC-Refrigerant Substitutes. Federal funding supporting the MCLR program constitutes 93.57% of allowable costs. Funding from the air-conditioning and refrigeration industry supporting the MCLR program consists of direct cost sharing of 6.43% of allowable costs and significant in-kind contributions."

EXECUTIVE SUMMARY

Lubrication properties of refrigeration lubricants were investigated in high pressure nonconforming contacts under different conditions of temperature, rolling speed, and refrigerant concentration. The program was based upon the recognition that the lubrication regime in refrigeration compressors is generally elastohydrodynamic or hydrodynamic, as determined by the operating conditions of the compressor and the properties of the lubricant. Depending on the compressor design, elastohydrodynamic lubrication conditions exist in many rolling and sliding elements of refrigeration compressors such as roller element bearings, gears, and rotors.

The formation of an elastohydrodynamic film separating rubbing surfaces is important in preventing the wear and failure of compressor elements. It is, therefore, important to predict the elastohydrodynamic (EHD) performance of lubricants under realistic tribocontact conditions. This is, however, difficult as the lubricant properties that control film formation are critically dependent upon pressure and shear, and cannot be evaluated using conventional laboratory instruments.

In this study, the elastohydrodynamic behavior of refrigeration lubricants with and without the presence of refrigerants was investigated using the ultrathin film EHD interferometry technique. This technique enables very thin films, down to less than 5 nm, to be measured accurately within an EHD contact under realistic conditions of temperature, shear, and pressure. The technique was adapted to the study of lubricant/refrigerant mixtures. Film thickness measurements were obtained on refrigeration lubricants as a function of speed, temperature, and refrigerant concentration. The effects of lubricant viscosity, temperature, rolling speed, and refrigerant concentration on EHD film formation were investigated. From the film thickness measurements, effective pressure-viscosity coefficients were calculated.

The lubricants studied in this project included two naphthenic mineral oils (NMO), four polyolesters (POE), and two polyvinyl ether (PVE) fluids. These fluids represented viscosity grades of ISO 32 and ISO 68 and are shown in the [table below](#). Refrigerants studied included R-22, R-134a, and R-410A. Film thickness measurements were conducted at 23 °C, 45 °C, and 65 °C with refrigerant concentrations ranging from zero to 60% by weight.

Refrigerant	Lubricant	Commercial Identification

R-410A	ISO 32 Polyolester (POE-32) ISO 32 Polyvinyl Ether (PVE-32) ISO 68 Polyolester A (POE-68A) ISO 68 Polyvinyl Ether (PVE-68)	ICI Emkarate RL 32H Idemitsu Kosan FVC 32B ICI Emkarate RL 68H Idemitsu Kosan FVC 68B

All of the lubricants studied behaved as expected from the EHD theory under air. EHD film thickness increased with speed and dynamic viscosity and decreased with temperature. Effective pressure-viscosity coefficients (α) calculated from the film thickness data showed the effect of chemical structure on the pressure-viscosity characteristics of the fluids. The fluids were ranked with respect to their pressure-viscosity coefficients in the following order:

naphthenic mineral oils > polyvinyl ethers > polyesters.

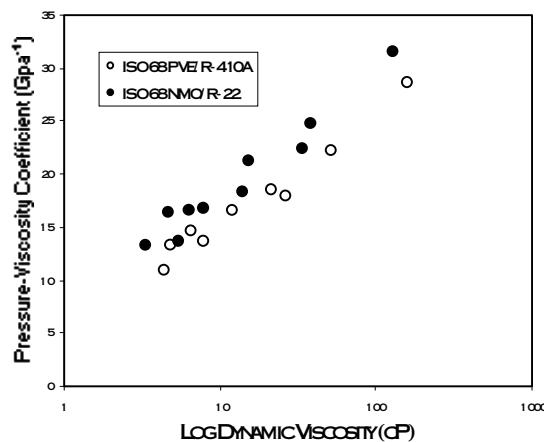

Differences were observed in the pressure-viscosity characteristics of the polyesters studied. This was related to the degree of branching in the ester structure. Esters with branching have higher α -values than those with linear structure. Effective pressure-viscosity coefficients also change with temperature, decreasing as the temperature increases.

Refrigerants have a significant effect on reducing the EHD film formation ability of lubricants. EHD film thickness decreases drastically in the contact as the refrigerant concentration in the lubricant increases. Even at the low refrigerant concentration of 10%, the reduction in film thickness ranges from 30 to 65% depending on the test temperature. Refrigerants reduce dynamic viscosity as well as the pressure-viscosity coefficients of lubricants. However, this effect decreases as the temperature increases. The thickness of the EHD film formed by the lubricant/refrigerant mixtures show a similar dependence on speed as that of the lubricant itself. Under some conditions (high refrigerant concentrations, high

temperatures and pressures), some deviations were observed from the EHD theoretical slope for the film thickness/speed relationship.

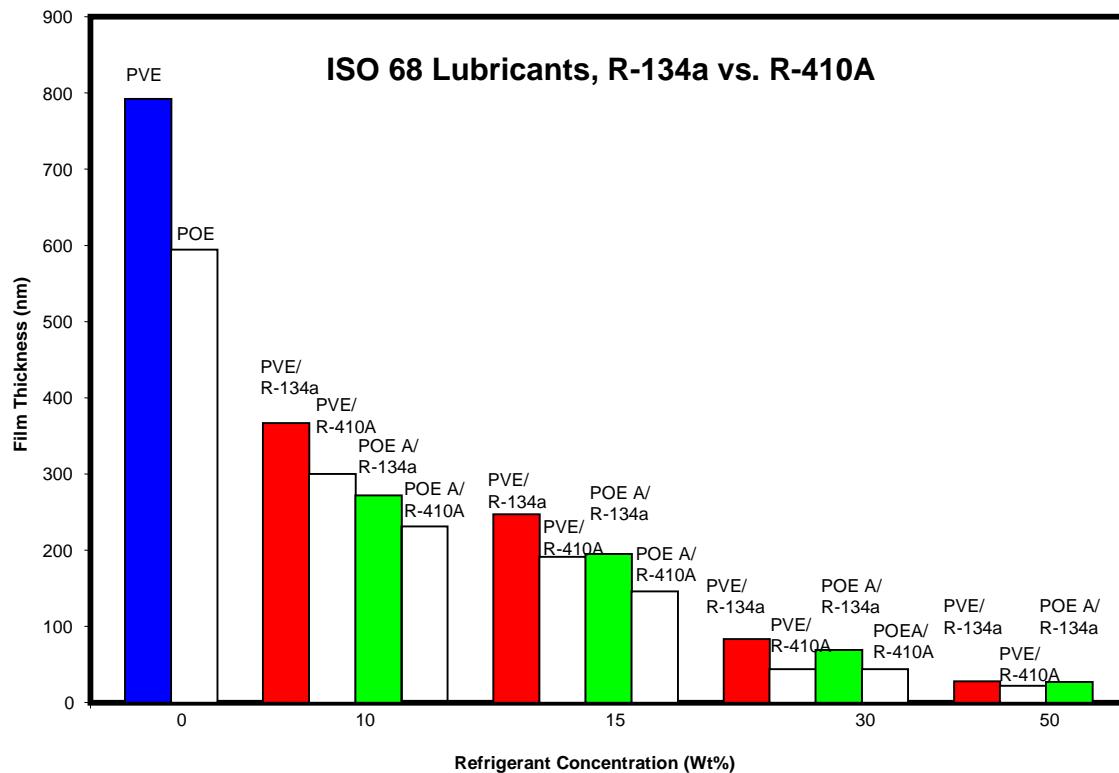

Effective pressure-viscosity coefficients for the lubricant/refrigerant mixtures were calculated from the film thickness data using the theoretical relationship of Dowson-Hamrock and dynamic viscosity data available for the mixtures in the literature. The accuracy of the calculated pressure-viscosity coefficients depends strongly on the accuracy of the dynamic viscosity data used in the calculations.

For a given refrigerant and lubricant mixture, pressure-viscosity coefficient increases linearly in proportion to the logarithm of dynamic viscosity as shown below. This finding suggests that the same fundamental molecular properties govern changes in both dynamic viscosity and pressure-viscosity properties of fluids.

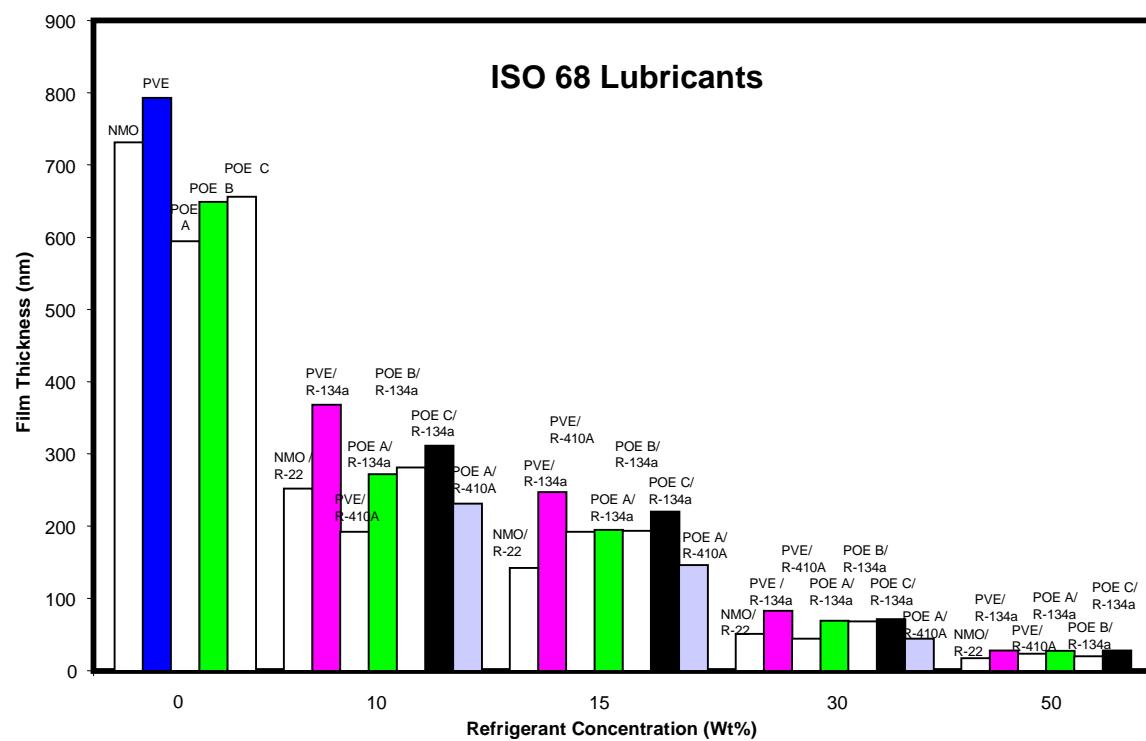

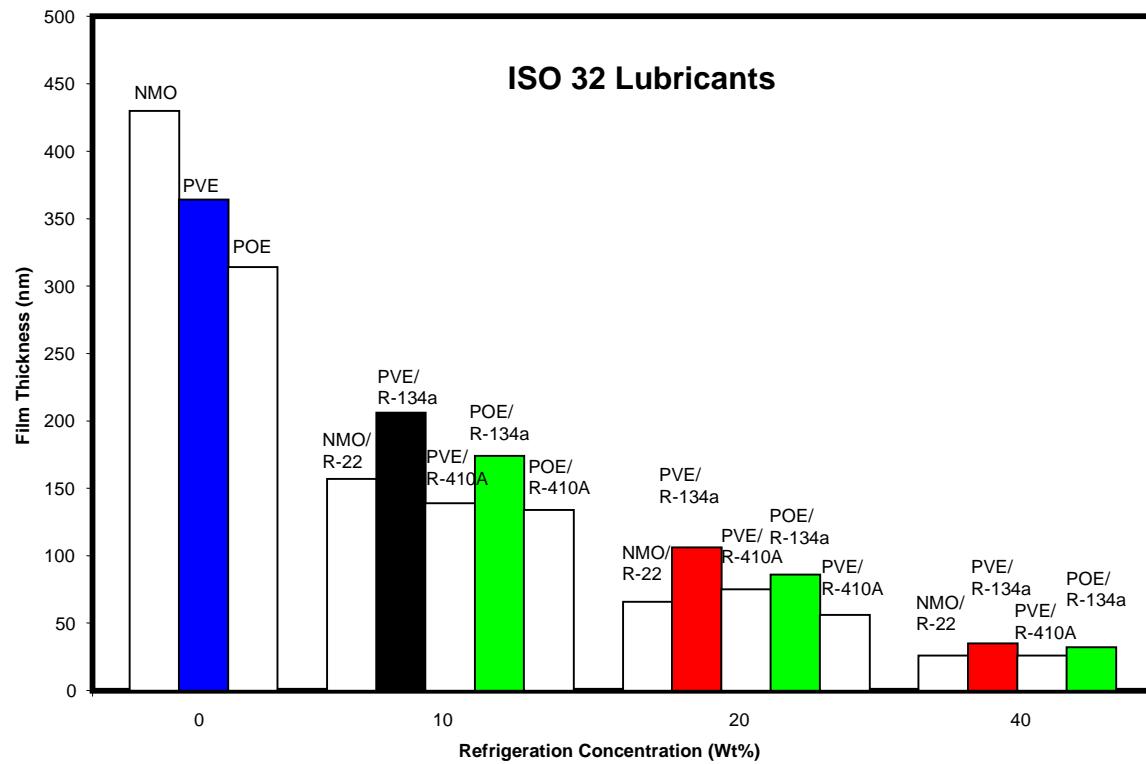

The ranking obtained with respect to the pressure-viscosity characteristics of the lubricants under air was also observed under refrigerant environments. However, the differences became smaller as the refrigerant concentration and the temperature increased. In general, refrigerant (R-134a or R-410A) mixtures with polyvinyl ethers have higher α -values than those with polyolesters. Mixtures of naphthenic mineral oil and R-22 have higher α -values than those of polyolesters or polyvinyl ethers and R-134a or R-410A.

The presence of R-410A in the lubricants (polyolesters or polyvinyl ethers) results in thinner EHD films, as shown below, than those produced by the same lubricants in the presence of R-134a.

A graphical ranking of all the tested lubricant/refrigerant combinations is shown in the charts below. The film thickness data reported in these charts were obtained under the same conditions of temperature (22.5 °C) and speed (0.8 m/s) for ISO 32 and ISO 68 lubricants and their mixtures with refrigerants.

Based on the results of the current study, future areas of investigation were identified. These areas concentrate on 1) ways to improve the accuracy of the dynamic viscosity and pressure-viscosity coefficient determinations on lubricant/refrigerant mixtures, and 2) evaluation of EHD friction (traction) properties of lubricant/refrigerant mixtures. This work would be useful for modeling viscosity and pressure-viscosity characteristics of lubricant/refrigerant mixtures, and for determining and optimizing lubricant behavior in EHD contacts of refrigeration compressors.

EXPERIMENTAL SECTION

Optical Interferometry

[Figure 1](#) shows the principles of optical interferometry as applied to an EHD contact. The EHD contact can be formed by a steel ball loaded against a flat disc as a contact geometry equivalent to many nonconforming contacts of practical importance. Either the ball or the disc can be driven to give varying slide-to-roll ratios, simulating conditions found in practice. The disc is transparent to visible light, and the EHD film generated is measured by the observation of interference color within the contact. This technique has been very useful in studying EHD behavior of lubricants since the wavelength of light is of the same order as a typical EHD lubricant film.

The surface of the glass disc shown in [Figure 1](#) is coated with a thin (20 nm) semi-reflecting chromium layer. Light is shone into the contact through the glass disc. Some of this light is reflected from the underside of the disc and some passes through the lubricant's film and is reflected back from the steel surface. Since the two beams of light travel different distances, when they recombine they interfere either constructively or destructively, according to [Equations 1 and 2](#) below, and produce colored interference patterns which are characteristic of the lubricant film thickness. The lubricant film thickness, which is represented by the optical path difference between the two beams, is determined by studying the intensity of the recombined beam.

Destructive interference:

$$h_{\text{oil}} = \frac{(N + \frac{1}{2} - \phi) \lambda}{2n \cos \theta} \quad N = 0, 1, 2 \quad \text{Equation 1}$$

Constructive interference:

$$h_{\text{oil}} = \frac{(N - \phi) \lambda}{2n \cos \theta} \quad N = 1, 2, 3 \quad \text{Equation 2}$$

where h = lubricant film thickness

N = fringe order

ϕ = net phase change

λ = wavelength of interfered light

n = refractive index of lubricant

θ = angle of incidence

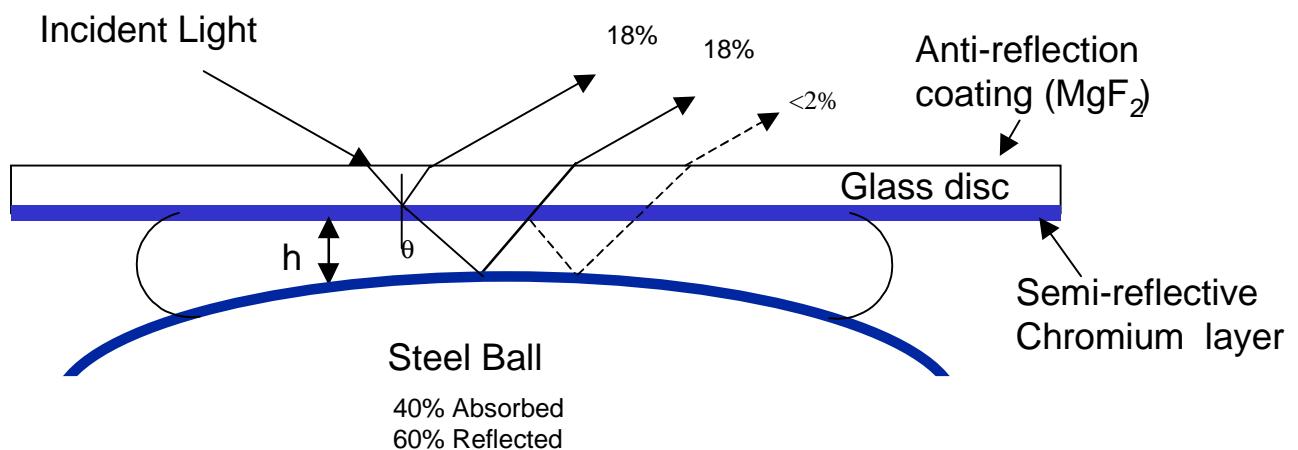

Figure 1. Principle of optical interferometry

The optical interferometry technique has been a useful tool for measuring lubricant film thickness in EHD contacts. This technique, however, also has some significant limitations with respect to the thickness of the films measured and the precision of the measurements. For example, for vertical illumination Equation 3 reduces down to the following equation for the first fringe:

$$nh_{oil} = \frac{\lambda}{4} \quad \text{Equation 3}$$

This indicates that the first fringe occurs at the wavelength of visible light divided by four, which means that the thinnest films that can be measured by conventional optical interferometry are around 80 to 100 nanometers. This limitation has been overcome by the development of the “ultrathin film EHD interferometry” technique which is described in [Section 5.0 \(1\)](#).

Ultrathin Film Interferometry Method – Lubricant Film Thickness Measurements

Ultrathin film interferometry method ([1](#)) was adapted to measure film thickness of lubricant and refrigerant mixtures. This method is an extension of conventional optical interferometry that permits very thin films, down to less than 5 nm, to be measured accurately within an EHD contact. This technique can be used to study lubricant behavior in EHD as well as in mixed lubrication regimes. It is particularly useful for measuring film thickness for low viscosity fluids and/or under high temperatures. It has been successfully applied to study the EHD behavior of lubricant base oils, antiwear additives, metalworking fluids and polymers used as viscosity index improvers in lubricants ([2-8](#)). Some preliminary studies were also conducted on refrigeration lubricants ([9](#)).

The test set-up is shown schematically in [Figure 2](#). A highly polished steel ball (AISI 52100, 19.05 mm diameter, 11 nm RMS surface roughness) is loaded against the underside flat surface of a rotating transparent glass disc to form a circular concentrated EHD contact. The underside of the chromium-plated glass disc is coated with a spacer layer of transparent silica of about 500 nm thickness. The composite surface roughness of the undeformed surfaces is 11 nm.

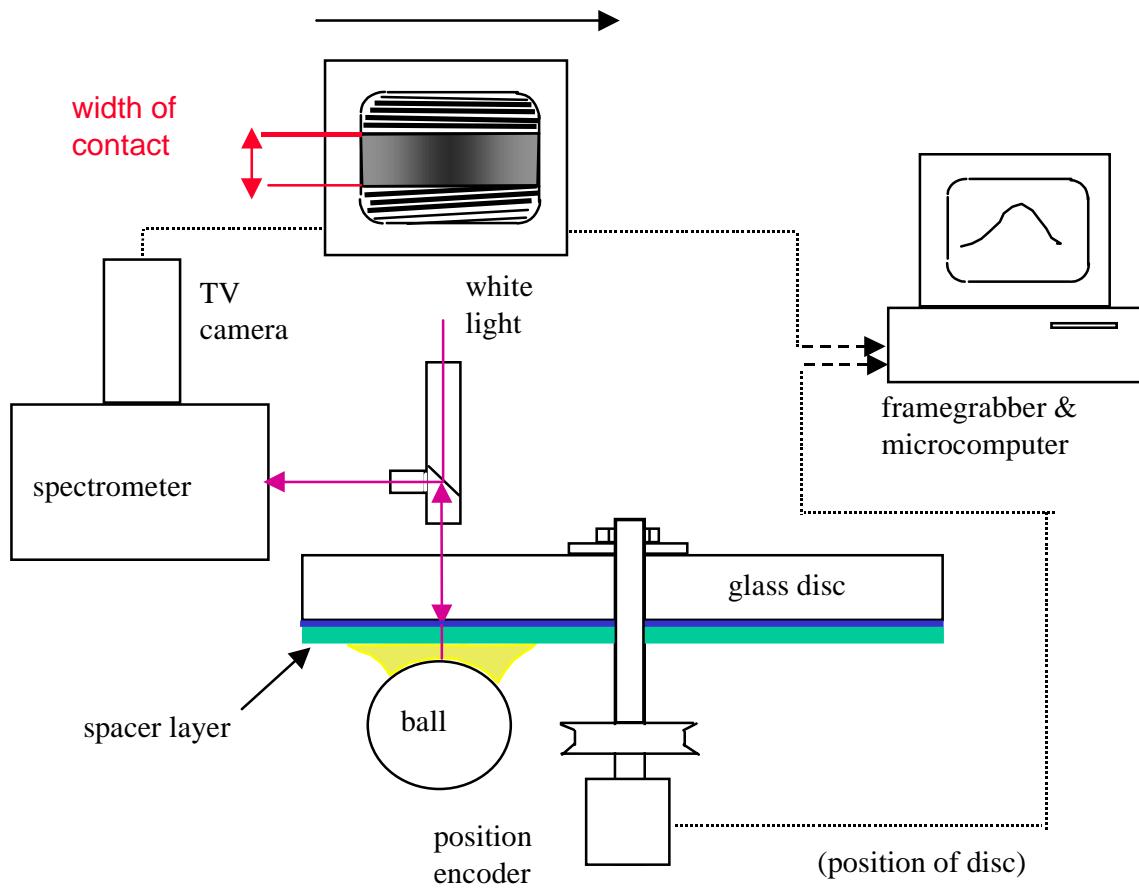

Figure 2. Schematic set-up for ultrathin film interferometry

The ball is contained in a lubricant bath and is driven by the disc in nominally pure rolling. The lubricant is filled halfway to the top of the ball, so that the lubricant is entrained into the contact by the rolling motion of the ball. The test lubricant is enclosed in a stainless steel chamber and a heat insulation lid sits on top of the glass disc. This helps to maintain constant test temperature and protects the lubricant from exposure to the outside environment. The test temperature is controlled using heating rods embedded in the chamber walls and is monitored near the contact inlet using a digital thermometer. The temperature can be controlled to a set value within ± 0.5 °C.

Lubricant film thickness is determined by optical interferometry as shown schematically in [Figure 3](#). White light is shone into the contact and some is reflected from the chromium layer, while some passes through the silica spacer layer and any lubricant film present to be reflected from the ball. The two beams recombine and interfere. The interfered light from the contact is passed into a spectrometer where it is dispersed and detected by a solid state, black and white TV camera as shown in [Figure 2](#). A framegrabber is used to capture this image and a microcomputer program determines the wavelength of maximum constructive interference in the central region of the contact. In this case, the maximum constructive interference of spacer layer plus lubricant film occurs when:

$$n_{\text{oil}} h_{\text{oil}} + n_{\text{sp}} h_{\text{sp}} = \frac{(N - \phi) \lambda_{\text{sp+oil}}}{2 \cos \theta} \quad N = 1,2,3 \quad \text{Equation 4}$$

Maximum constructive interference of spacer layer occurs when:

$$n_{\text{sp}} h_{\text{sp}} = \frac{(N - \phi) \lambda_{\text{sp}}}{2 \cos \theta} \quad N = 1,2,3 \quad \text{Equation 5}$$

The lubricant film thickness is then calculated from the difference between the measured film thickness and the thickness of the silica spacer layer:

$$h_{\text{oil}} = \frac{(N_{\text{sp+oil}} \lambda_{\text{sp+oil}} - N_{\text{sp}} \lambda_{\text{sp}})}{2n_{\text{oil}}} \quad N = 1,2,3 \quad \text{Equation 6}$$

The ultrathin film technique incorporates two important advances over conventional optical interferometry. The first one is the use of a transparent silica spacer layer which acts like a supplementary oil film, enabling optical interference to be observed even when the actual oil film present is very thin. This overcomes a major limitation of conventional optical interferometry, that it cannot easily measure film below approximately one quarter the wavelength of visible light. Thus, lubricant films less than 100 nm (0.1 micron) thick cannot be measured using the conventional method. The second advance is that the reflected interfered light is dispersed by a spectrometer rather than being observed by the eye, as is done in

conventional optical interferometry. The dispersed spectrum is computer-analyzed to identify the wavelength of light that is most constructively interfered. This greatly increases the precision of the method compared to conventional optical interferometry.

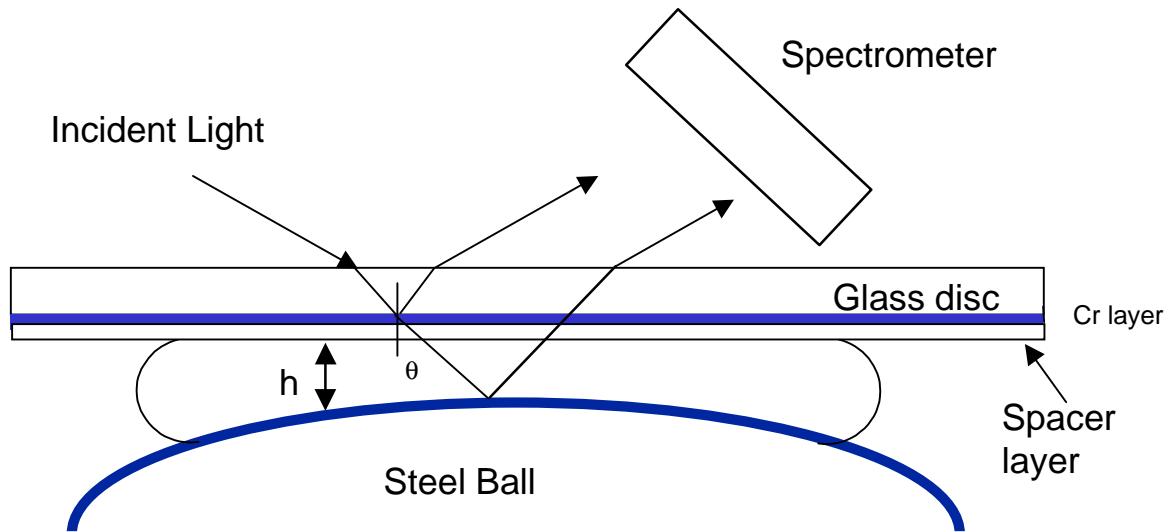

Figure 3. Principle of ultrathin film interferometry

Film Thickness Measurements for Lubricant/Refrigerant Mixtures – Pressurized Test Rig

The ultrathin film EHD rig was modified to operate at pressures above the vapor pressure of the refrigerants at the test temperatures. For this purpose, a new stainless steel test chamber with thicker walls (20 mm) was constructed. This chamber was fitted with a heavy section bolt-down lid with a nitrile O-ring and a small (25 mm diameter) fused silica insert to view the contact, as shown in [Figure 4](#). The fused silica window was sealed with a nitrile O-ring and a copper washer to prevent stress cracking of the window due to misalignment. The optics were adjusted to compensate for the longer focal length as compared to the atmospheric system. The chamber was fitted with a new shaft and seal assembly. The seal assembly consisted of a high pressure bellows seal with graphite face. A solid-based chamber with no aperture for the load system was designed. A spring loading system with parallel leafs was fitted inside the chamber. When the ball and disc were placed and clamped in the chamber, the

springs deflected and applied a constant load of 20N to the contact. The chamber was fitted with heating rods, cooling galleries, an inlet valve, an adjustable pressure relief valve, and an emergency burst valve.

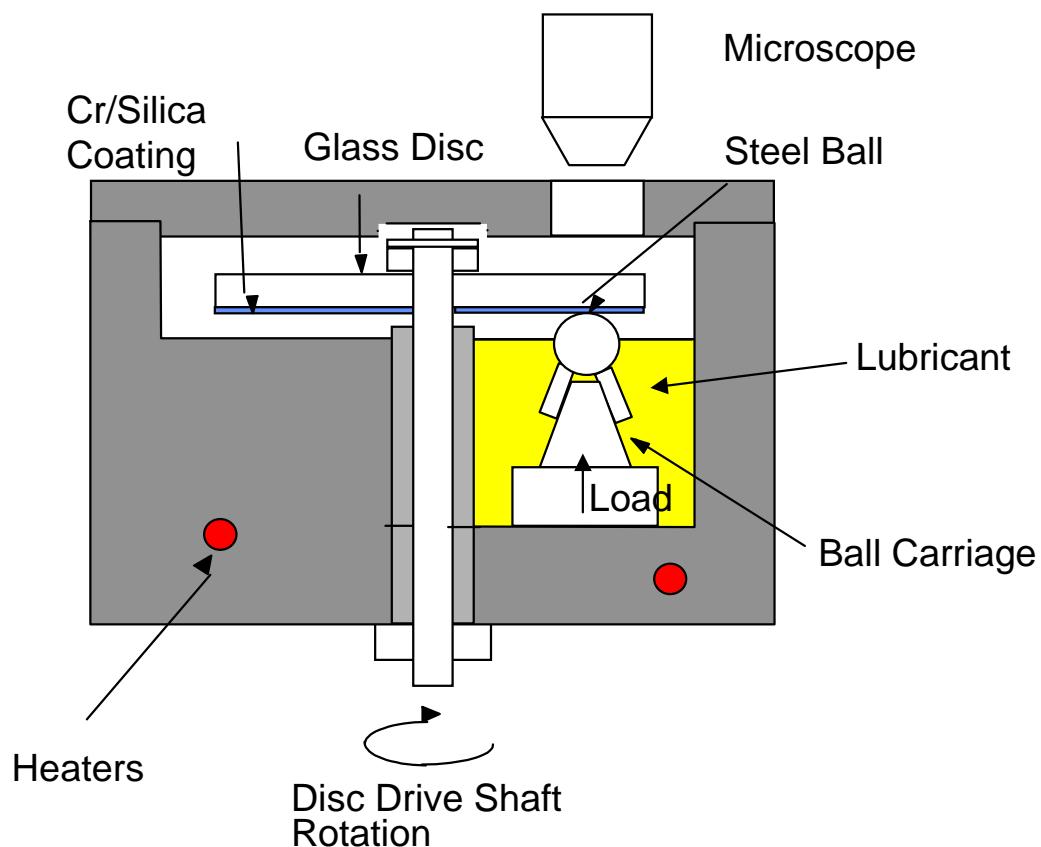

Figure 4. Pressurized Ultrathin Film Interferometry Rig

[Figure 5](#) is a simplified diagram showing the test set-up for refrigerant/lubricant mixtures. The refrigerant cylinder was placed on a balance with a resolution of ± 0.05 g. The cylinder was connected to the test chamber by a 4.76 mm ID flexible stainless steel tubing. A known amount of refrigerant was introduced into the test chamber by a needle valve, V2. The system was designed to operate under 25 bars of pressure. The externally adjustable pressure relief valve was set at 35 bars. The emergency burst valve was rated at 50 bars. The system was fitted with vent and vacuum lines with needle valves for degassing the lubricant and discharging the refrigerant.

Test Procedure and Conditions

The test conditions are shown in [Table 1](#). Film thicknesses of lubricants and refrigerant/lubricant mixtures were measured between the ball and the disc using ultrathin film interferometry as described above at a series of rolling speeds ranging from 0.01 m/s (2 rpm-disc rotational speed) to about 2 m/s (460 rpm). All of the tests were carried out at a load of 20N. For the glass-on-steel contact, this load resulted in a maximum Hertz contact pressure of 0.54 GPa.

Table 1. Test Conditions and Materials

Contact Materials	52100 steel ball (19 mm diameter) SiO_2 coating (~ 400 nm) on Cr coated glass disc
Contact Load	20 N
Maximum Contact Pressure	0.54 GPa
Rolling Speed	0.01 to 2 m/s
Bulk Temperature	23 °C, 45 °C, 65 °C

The film thickness was measured at three fluid temperatures: ambient, 45 °C, and 65 °C. The ambient temperature varied from 22 °C to 25 °C between tests. The variation in the ambient temperature for each test was within ± 0.5 °C. The average temperature for each ambient temperature test was reported along with the data. The test temperature of 45 °C and 65 °C was controlled to a set value within ± 0.5 °C using a small K-type thermocouple with a resolution of 0.1 °C near the contact inlet. A new steel ball of RMS surface roughness of 11 nm was used for each test.
